ABSTRACT

Introduction: Timely assessment and treatment of back pain is therefore essential to relieve the patient's pain and distress to decrease the likelihood of long term disability. In view of this, the present study was undertaken to clinically evaluate the clinical features and roentgenographic findings in patients with low back pain.

Material and Methods: The present case series study was conducted among 25 consecutive patients with low back pain for 1 month duration who were not responding to conservative treatment. A detailed history were taken, clinical examination was conducted. Inspection in standing posture was done. To measure the range of motion of the lumbar spine, four movements were performed –flexion, extension and side bending. The straight leg raise (SLR) test was used to evaluate for lumbar nerve root impingement or irritation. For radiological assessment, standard radiographic positioning was maintained in all the radiographs. The data so obtained was evaluated using SPSS-16 and was evaluated accordingly.

Results: Average age of the patients was 32.5 years. 44 % patients were in the 3rd decade and 40% were in the 4th decade. Male and female patient's ratio was 5.25:1. Majority of patients (48 %) were labourer followed by 24% farmer. Majority(56%) patients had no tenderness on palpation. 56% patients had moderate degree of restriction of lumbar flexion, 48% patients had restriction of extension and 36 % patients

had restriction of lateral flexion. Significantly positive passive SLR test was present in 56 % patients.

Conclusion: Clinical examination is an important tool for assessment of patient's disability, especially to support and exclude organic lesions X-rays are an essential and cost effective initial screening tool. Patients having significant symptoms and definite findings but normal looking X rays, need further imaging studies in the form of MRI.

Keywords: Low back pain; Range of movement (ROM); SLR test.

INTRODUCTION

Low back pain is a common musculoskeletal condition with lifetime prevalence reported to be about 85% in developed countries and has been a major public health burden for many years, generating substantial work disability and healthcare costs¹. Among adults in the general population, 70 to 85 % are believed to experience at least one episode of low back pain at some time during their life,² while approximately 14% experience serious low back pain i.e. pain persists for more than 2 weeks³ and nearly 8% reporting at least one episode of severe acute low back pain.⁴ Low back pain is a prominent problem for medical practitioners as most patients will have at least one episode at some point in their lives.⁵ Although low back pain usually resolves spontaneously within 1 to 4 weeks, approximately 33 % of individuals with low back pain

continue to have moderate to severe pain 1 year later, and approximately 20 % of patients with low back pain have pain that is severe enough to cause substantial limitations of normal activities.^{2,6} Timely assessment and treatment of back pain is therefore essential to relieve the patients pain and distress to decrease the likelihood of long term disability. In view of this, the present study was undertaken to clinically evaluate the clinical features and roentgenographic findings in patients with low back pain.

MATERIAL AND METHODS

The present study was conducted among 25 consecutive patients with low back pain for 1 month duration who were not responding

to conservative treatment, and also had no reason to suspect any underlying organic disease in Orthopaedic department of P.B.M. Hospital attached to S.P. Medical College, Bikaner. Each patient was analyzed on the basis of history; physical examination and a base line X-ray were taken.

Patients with any organic musculoskeletal or neurological disorder and with spinal deformity were excluded from the study. A detailed history were taken, clinical examination was conducted. Inspection in standing posture was done. To measure the range of motion of the lumbar spine, the distance travelled by tips of finger

over the lower limb was observed. Trunk movement is a compound movement, involving intersegmental motion and hip motion; measurements were taken by stabilizing the pelvis during movement.

The participants were required to stand erect with their knees extended and their feet 15 cm apart. Four movements were performed –flexion, extension and side bending. As clinical grading of range of movement (ROM) was not found in available literature, the following grading system was developed for measurement:

Score	Range of Movement			
	Flexion	Extension	Right side bending	Left side bending
0	Fingertip up to knee	0-10 degree	Mid-thigh	Mid-thigh
1	Fingertip up to leg	10-20 degree	Knee	Knee
2	Fingertip up to floor	20-30 degree	Below knee	Below knee

Grade 0: No Flexion Restriction

Grade1: Mild: Patient touches both knee and foot but not floor.

Grade2: Moderate: Patient touch knee and leg but not foot.

Grade3: Severe: Patient cannot bend at all.

The straight leg raise (SLR) test was used to evaluate for lumbar nerve root impingement or irritation. This is a passive test in which each leg was examined individually. With the patient in the supine position, the knee was extended and the hip was flexed until a complaint of pain or tightness was reached. The leg was then carefully returned to the table and the contra lateral leg was tested in a similar manner. Grading of the test was done in the following manner:

Grade III: Angle <30 degree

Grade II: Angle 30-60 degree

Grade I: Angle >60 degree

Grade Zero: Negative

Palpation for midline spinal tenderness and paraspinal tenderness was done according to a standard method and grading was done

in the following manner. Spinal tenderness was classified into four grades according to the reaction (facial and verbal) of the patient during examination.

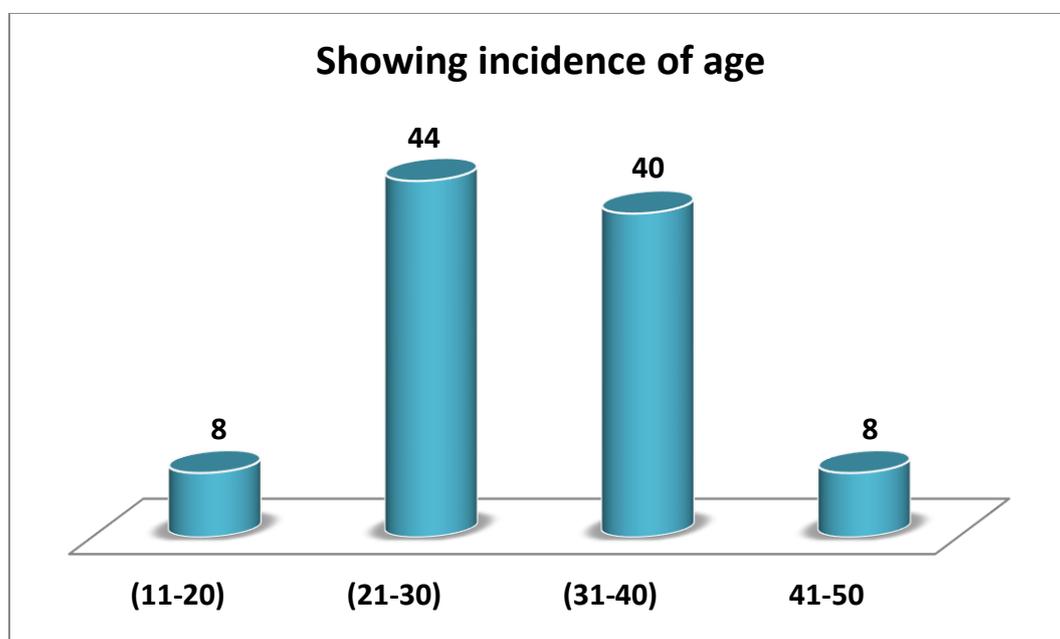

Grade I: Mild -The patient says that the part is painful on pressure.

Grade II: Moderate -The patient winces on pressure.

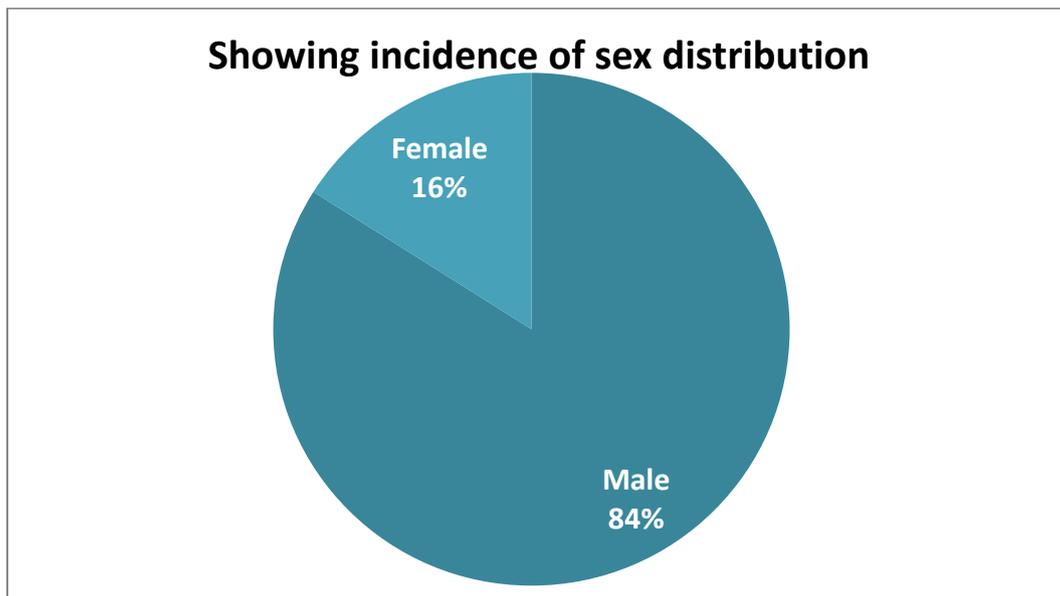

Grade III: Severe -The patient winces and withdraws the affected part.

Grade IV: Extreme-The patient will not allow the part to be touched.

For radiological assessment, standard radiographic positioning was maintained in all the radiographs. All the radiographs were taken in the erect position with centering at the L3 level. To minimize radiation dose the lumbosacral X-ray for LBP were routinely limited to anteroposterior and lateral views. In radiographs the list, lordosis and scoliosis were recorded. The data so obtained was evaluated using SPSS-16 and was evaluated accordingly.

Graph 1: Incidence according to age

Graph 2: Showing incidence of sex distribution

Table 1: Distribution of patients according to occupations

Occupation	No. of patients	Percentage
Labourer	12	48
Housewife	3	12
Nonworking	2	8
Sedentary worker	2	8
Farmer	6	24
Total	25	100

Table 2: Showing incidence of Spinal Tenderness

Grade of tenderness	No. of patients	Percentage
0=None	14	56
1=Mild	5	20
2=Moderate	3	12
3=Severe	3	12
4=Extreme	0	0
Total	25	100

Table 3: Showing grade of spinal flexion

Grade of flexion	No. of patients	Percentage
0=None	1	4
1=Mild	10	40
2=Moderate	14	56
3=Severe	0	0
Total	25	100

Table 4: Showing Extension ROM

Extension ROM	No of patients	Percentage
Restricted	12	48
Not restricted	13	52
Total	25	100

Table 5: Showing side bending ROM

Bending ROM	No. of patients	Percentage
Restricted	9	36
Not restricted	16	64
Total	25	100

Table 6: Showing passive SLR Test

Passive SLR Test	No. of patients	Percentage
Positive	14	56
Negative	11	44
Total	25	100

RESULTS

Average age incidence in this study group of 25 patients was 32.5year. The majority of patients were in the 3th (44%) and 4th decade (40%) and only 16% in the 2nd and 5th decade (graph 1). Regarding sex distribution, it was found that affected female and male was 1:5.25 with a male predominance (graph 2). Regarding occupation profile, it was found that majority of low back pain patients were labourer (48%) followed by farmer and house wife 24% and 12% respectively. Lowest incidence were found in nonworking and sedentary workers each had equal percentage (16% each) (table 1). During clinical examination of the lumbar spine, it was found that no patient showed abnormal lumbar curvatures i.e. lumbar scoliosis and lumbar lordosis. 56% patients had no tenderness on palpation while mild tenderness was present in 20% patients (table 2). Regarding range of motion of lumbar spine, the majority of patients (56%) showed moderate restriction of lumbar flexion, 48% of patients showed restriction of extension and 36% showed restriction in range during side bending. Majority of patients (96%) had mild to moderate restriction of flexion. Majority of patients (64%) had no restriction of bending. We observed that restricted and non-restricted extension range of motion patients are almost equal in numbers (table 3-5). 56 % of patients showed significantly positive passive SLR test on examination (table 6). The lumbo-sacral radiographic examination revealed that no patient showed abnormal lumbar curvatures i.e. lumbar scoliosis and lumbar lordosis.

DISCUSSION

Low back pain is one of the leading causes of health problems in India. A widely accepted definition of low back pain is pain, stiffness or muscle tension in the lower back, below the costal margin and above the inferior gluteal folds with or without leg pain.

It is pain in the lower back area related to the lumbar spine, the discs between the vertebrae, the ligaments around the spine and discs, the spinal cord and nerves and muscles of the lower back. There are two common groups of low back pain – specific back pain and non-specific or mechanical low back pain.⁷⁻¹⁰

There are so many studies done till date on back pain where the patient is evaluated by clinical examination and with a back pain questionnaire whereby the disability status is assessed.⁶ In our day to day OPD also the patients with complain of low back pain were assessed with a brief relevant history and a clinical examination followed by x-rays of the lumbo-sacral spine to assess the radiological picture.

The problem of low back pain not only has a greater incidence but also the handicap in daily living is more pronounced because of life style requirements. In the Indian household women have significant floor working for which they have to squat and sit cross legged. The male population is mostly doing manual work and their jobs also require a lot of squatting, bending and heavy weight lifting. The higher incidence of low back pain in the urban population is because of overall poor physical activity with excessive episodic strains. Approximately 85-90% of low back pain are non-pathological in nature.⁴ It is also called mechanical low back pain and causes significant level of work absenteeism. This needs to be analyzed properly so that man-hour losses are minimized and frequency of sick leave can be reduced.¹¹

In our study, the majority of patients (84%) were in the 3rd and 4th decade i.e. 44% in the 3rd and 40% in the 4th decade. The average age was 32.5 years, minimum age was 18 years and maximum age was 50 years. Similarly, Julie M et al¹² conducted a similar study and reported average age of 39.2 years and Walden A et al¹³ reported average age of 36.5 years. Tagawachi T et al¹⁴ conducted a similar study and found that a higher incidence of low back pain in young and middle aged people. Also people in this age group are highly active in daily life and are exposed to various stresses.

Regarding sex distribution, the present study found that male were more affected than female patients with back pain and the ratio of female and male patients was 1:5.25. Similar findings were seen in the study conducted by Wilson ES et al,¹⁵ Sandhu HS et al¹⁶ and Altinel L et al¹⁷ found the affected male patients population was more than female. In our study male patients affected were mainly labourers and farmers who were involved in more bending, weight lifting activities. Moreover, female patients in our setup have an overall lesser OPD attendance which is mainly attributed to conservative social norms.

Regarding distribution of occupation, we found that the majority of patients were labourers (48%) and farmers (24%) followed by housewives (12%). Similar findings were seen in the study conducted by Shakoor M et al,¹⁸ Abdul Bari et al,¹⁹ Altinel L et al,¹⁷ Sadigia A et al,²⁰ and Bihari V et al.²¹ Cotton A et al²² also reported that low back pain problems were more common in subjects who performed heavy physical work and particularly in those jobs that involve kneeling and squatting.

During assessment of patients by a clinical examination like range of motion, forward flexion and extension, SLR, spinal tenderness as measured by the investigator, we found correlation between some of the activities like forward flexion.

Similar correlation was also found by Steinberg EL et al.²³ Clinical examination is an important tool for assessment of patients especially to support and exclude destructive and compressive

lesions and also neurological diseases. For example in case of back pain when there may be ubiquitous symptoms on questionnaire, then clinical examination is helpful in revealing spasm/restriction of mobility/neurological deficit indicative of an underlying pathological condition.

X rays are an essential part of the examination in case of back pain since they can be easily taken anywhere, and are cost effective for screening purposes. X rays help in ruling out/detecting destructive lesions.

CONCLUSION

Clinical examination is an important tool for assessment of patient's disability, especially to support and exclude organic lesions. 56% patients had moderate degree of restriction of lumbar flexion, 48% patients had restriction of extension and 36 % patients had restriction of lateral flexion. Significantly positive passive SLR test was present in 56 % patients. X-rays are an essential and cost effective initial screening tool. Patients having significant symptoms and definite findings but normal looking X rays, need further imaging studies in the form of MRI.
